Lamproderma puncrliculatum, a new species of Myxomycetes

MARJA HÄRKÖNEN

A new species of Myxomycetes, Lamproderma puncrliculatum Harkonen, is described from Finland. It has dark brown spots on the peridium and the capillitium is light brown throughout. It was growing on living sporophores of Cantharellus tubaefomis Fr.

Marja Härkönen, Department of Botany, University of Helsinki, Unioninkatu 44, SF-00170 Helsinki 17, Finland

Lamproderma puncrliculatum Härkönen

n. sp. — Figs. 1—4

Sporangia gregarious, altitudine tota 0.5—1.3 mm. Sporangium globosum, 0.4—0.8 mm diam. Peridium membranaceum, persistens, argenteo-cine­ reum, iridescens, cum punctis saturate brunneis. Hypothallus discoideus, concolorus peridio. Stipes crassus, altitudine 0—0.5 mm, longitudinaliter sulcatus, concolorus peridio. Columella nigra, truncata, usque ad 1/3 vel ad 1/2 sporangii porri­ gens. Capillitium pallide brunneum, ramificans, anastomosans. Sporae universae saturate cupreaceo­ brunneae, luce transmissae purpureo-brunneae, verruculosae, 12.5—13.2—14 μm diam. Plasmodium ignotum.

In October 1974 Mr. M. Korhonen, conservator of the Botanical Museum of the University of Helsinki, brought me two sporophores of Cantharellus tubaeformis Fr., 3.X.1974 Mauri Korhonen (H holotype, TEX isotype).

Sporangia gregarious, globose, short-stipitate, total height 0.5—1.3 mm. Head of sporangium 0.4—0.8 mm. Peridium membranous, rough, persistent, irregularly splitting; dark silvery grey (according to Maerz & Paul 1950, Gunmetal 48 C 2) to the naked eye, under the dissecting microscope irides­ cent with blue, gold, green and red, and having dark brown, non-iridescent depressions. Stalk 0—0.5 mm high, thick, furrowed, concolorous with peridium. Hypothallus strong, discoid, concolorous with peridium and partially merging with adjacent hypothallus. Columella black, robust, cylindrical, extending through about 1/3—1/2 of sporangium. Capilli­ tium arising from apex of columella, light brown throughout, dividing and anastomosing and with many free ends. Thickness of threads 3—8 μm at base, less than 3 μm at apex. Spores globose, dark brown in mass, purple brown in transmitted light, spinulose, 12.5—13.2—14 μm in diam. Plasmodium unknown.

Type: Finland. Uusimaa, Espoo: Myllykyla at altitude of less than 50 m, in coniferous forest on living sporophores of Cantharellus tubaeformis Fr., 3.X.1974 Mauri Korhonen (H holotype, TEX isotype).
having larger sporangia, over 1 mm in diam. and a dark brown capillitium. *L. griseum* is distinguished by peculiar morchelloid reticulate ridges on the peridium, a long stalk and a capillitium that is violaceous with paler bases and apices. The nearest species, *L. gulielmae* (Meylan 1919, type: Switzerland: Jura Mts.; LAU), differs from the present specimen in the following main characters: The stalk of *L. gulielmae* is longer and thinner, the spots on the peridium are larger, the capillitium is still paler and the spores are strongly echinulate.

So the present specimen clearly belongs to a new species, whose distinctive characteristics are the silvery grey peridium with small dark brown spots,
relatively short and thick stipe, entirely light brown capillitium and purple brown spinulose spores.

I tested the viability of the spores of the specimen (see Kalyanasundram 1974) by cultivating them in hanging drops (Smart 1937). Many swarm cells developed, but after transfer to different agar plates (Howard 1931, Indira 1969), they failed to produce plasmodia. The plasmodium of the species is thus unknown, but a clue to its colour was obtained, as the sporangia included some immature ones (Fig. 2), which were milky white with brown spots.

Acknowledgement. — I want to thank Professor C.J. Alexopoulos for looking at the specimen, and also for showing it to Dr. D.T. Kowalski and encouraging me to describe it.
